The code structure written for a part of the project is given in the figure. The desired probability value of 10 million bits of the code was obtained. Then a1 and a2 are written onto the ai labels according to the turn-on output bits. The average bit energy is given as 1 joule. Other values can be derived from the results obtained in the analytical solution. Our simulation and analytical result is divided from 0 to 18 dB and its cycle is in the table in the code. The cyclic power of each dB costs, the mixture itself simulates sigma and the comparator circuit. The comparator circuit simulation is carried out on the gamma calculated by the code on the 'siAllValues' variable. To obtain the mixture (z = ai + no) noise, the problems posed by Gaussian arise. The strength of his body and his equations are obtained through the z variable. The 'randn()' function was used to obtain the Gaussian state. In the last part of the code, each analytical result was obtained by writing the Q() function we obtained analytically within the loop. The simulation shape obtained for a) is as shown in 1.

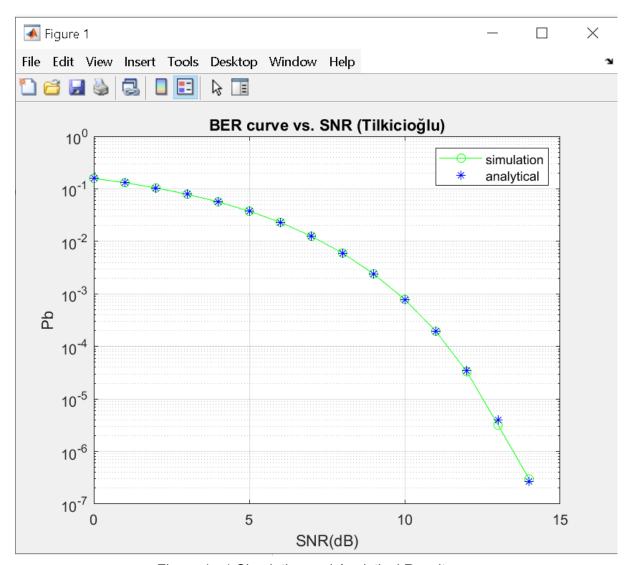

Figure 1: a) Simulation and Analytical Results

b) side code:

```

For option b, the exact code in option a was used. Only the desired bit probabilities have been changed. Figure 2 shows the output of the code for option b.

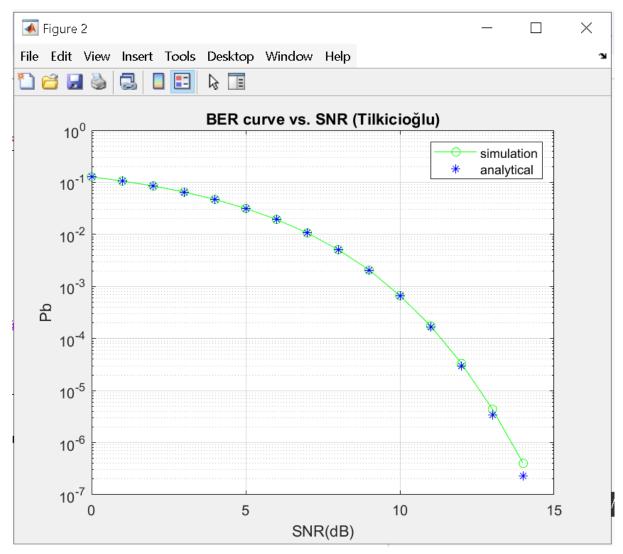

Figure 2: b) Simulation and Analytical Results

Interpretation of Simulation and Analytical Results:

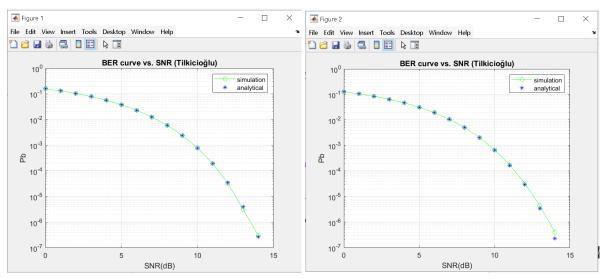

Figure 3: Analytical and Simulation Results in Both Cases

Similar results were obtained from simulation and analytical results for both probability cases. This is because their Eh's are the same. We can see that the bit error appearance of the SNR values of the table decreases, and this is valid for both cases. The analytical function calculated with the Q function was predicted very well in the simulation. Due to its characteristics, very small deviations occur. Tables for the values in the table When the SNR is 10 dB, our bit error probability is approximately 1 bit in 1000 bits.
